ABSTRACT
In the research, graphitic carbon nitride (g-C₃N₄) was synthesized using modified halloysite via a calcination method. The improvement of photocatalytic activity mainly benefits from the reduced e-/h⁺ pairs recombination rate, the improved electron separation yield. The photocatalytic activity of nanocomposite was evaluated through the Synozol red HF-6BN dye degradation, the degradation efficiency approached 99% after 30 mins irradiation under the solar light, and the performance is slightly reduced to 94% after three consecutive tests. These results have demonstrated an effective method to synthesize g-C₃N₄ photocatalysts with nanostructures using crude clay minerals.

Introduction
In recent years, there has been much research using different methods to treat toxic organic compounds in water such as mechanical, biological, physical chemistry methods,... The biological method is evaluated as the most economical when compared to physical chemistry, mechanical methods [1]. However, their applicability is limited due to the long processing time and ineffective with high molecular structure [2]. Recently, photocatalysis was nominated as a superior method that active under visible light, capable of degradation organic compounds, thoroughly degradation complex colored substances. In addition, this method has other advantages as consuming less energy, ease of use and less toxic [3]. Most photocatalytic materials are based on metal oxides, typically TiO₂ [4], Fe₂O₃ [4], CdS [5], BiₓWO₆ [6] – these substances are active only under UV light, accounting for only 5% of solar energy. Furthermore, metal oxides cannot respond to the sustainability requirement due to their high cost, and scarcity [7]. Hence, the researchers find a new type of sustainable, inexpensive catalysts and can operate under visible light. Non-metallic semiconductors-graphitic carbon nitride (g-C₃N₄) receives much attention because of their photocatalytic reactivity in the wide light region, low fabrication costs, ease of synthesis, and possible green synthesis, non-toxic, chemical stability, and narrow bandgap energy (approximately 2.7 eV) [7]. g-C₃N₄ is easily prepared by thermal polymerization from nitrogen-rich precursors such as melamine, dicyandiamide, cyanamide, urea, thiourea, and ammonium thiocyanate [8]. However, the disadvantages of g-C₃N₄ have limited their applications in the field of photocatalyst like low surface area [9], the fast recombination rate of the e-/h⁺ pairs [10], low electron separation yield [11]. To improve these limitations, several methods have been proposed to create mesoporous materials [12], doped with metallic or non-metallic elements [13][14], magnetized with the magnetic material [15][16].

https://doi.org/10.51316/jca.2021.064
In addition, the use of natural mineral sources as support agents is also a new approach direction. Halloysite (Al₂Si₂O₅(OH)₄·nH₂O, HNT) is a natural aluminosilicate clay mineral and usually exists as tubes. Halloysite tubes have different surface chemistry on the internal and external: the internal surface of HNT is composed of gibbsite octahedral sheet (Al-OH) groups and is positively charged, while its negatively charged outer surface consists of siloxane groups (Si-O-Si). Halloysite tubes are rolled to form cylinders as a result of the strain caused by lattice mismatch between adjacent silicon dioxide and aluminum oxide sheets [17].

The combination of g-C₃N₄ photocatalyst and halloysite tubes was synthesized by Wenbin Wang et al. [18] through vapor deposition method. The results show that the separation efficiency of H₂ from water is 633 μmol g⁻¹ h⁻¹ under light irradiation, the higher 14.3 times that pure g-C₃N₄. The improvement of the photocatalytic activity was mainly due to the enlarged specific surface area and the decrease in the photogenerated electron-hole pairs recombination rate when g-C₃N₄ was modified by halloysite tubes. This study is the first step for the synthesis of composite materials based on g-C₃N₄ and halloysite clay minerals for environmental treatment.

Hence, a facile calcination route was proposed to synthesize the novel visible-light-responsive g-C₃N₄/HNT composite. In this study, the combining process of g-C₃N₄ with halloysite tubes was researched. The photodegradation tests were performed on Synozol red HF-6BN and the proposed mechanisms of enhancement of photocatalytic activity were also investigated.

**Experimental**

**Reagents**

[Image: Figure 1: Structure of Synozol red HF-6BN]

Urea (>99%), halloysite (>99%), H₂O₂ (30%), and Synozol red HF-6BN dye (>99%) were supplied by Sigma-Aldrich. All chemicals and reagents in this research used without any further purification.

**Preparation of graphitic carbon nitride (g-C₃N₄)**

The g-C₃N₄ was obtained through calcination with urea as a precursor. Typically, 5 g urea was put into a ceramic crucible, placed in a muffle furnace and heated at 500 °C for 2 h at the heating of 5 °C.min⁻¹ and then cooled to room temperature. The g-C₃N₄ has obtained a yellow powder.

**Preparation of g-C₃N₄/HNT composite**

The g-C₃N₄/HNT composite was synthesized by calcination method. Typically, three different amounts of urea (2 g, 3 g, and 4 g with weight percentages of g-C₃N₄ were 30%, 40%, 50%, respectively) and 2 g HNT was put into a ceramic crucible with a cover, placed in a muffle furnace and heated at 500 °C for 2 h at the heating of 5 °C.min⁻¹ and then cooled to room temperature. The obtained composites were labeled as 30%, 40%, and 50% g-C₃N₄/HNT.

**Characterization**

The crystal lattice structure of the synthesized samples was determined by X-ray powder diffraction (XRD) using a D8 ADVANCE system (Cu Kα1 copper radiation, λ = 0.154 nm, 3° min⁻¹ scanning speed, Bruker, Germany). Surface morphology was observed by a scanning electron microscope (S-4800, Hitachi). The Fourier transform infrared spectra (FT-IR) were measured with an FT-IR Affinity-1S (SHIMADZU). The UV-vis diffuse reflectance (UV-vis DRS) and were recorded with the UV-2600 spectrophotometer (Shimadzu). The Brunauer-Emmett-Teller (BET) specific surface area was determined at liquid-nitrogen temperature (77 K) using the N₂ adsorption-desorption technique on a ChemBET-3030 system.

**Photocatalytic experiments**

Photocatalytic activity of the sample was evaluated by degradation of Synozol red HF-6BN under solar irradiation. Typically, 100 mg of the catalyst was dispersed in 30 mL of the dye solution. The solution mixture was placed in the dark for 30 mins to reach the adsorption-desorption equilibrium. The initial concentration (C₀) was taken at this point. Then, the

https://doi.org/10.51316/jca.2021.064
mixture was illuminated under solar light for 30 mins. After every 5 mins, the small quantity of the solution was taken and measured under UV-Vis spectrometer to record the concentration \(C_t\) at maximum wavelength \(\lambda = 541\) nm. The conversion of dye was calculated using Equation 1:

\[
\text{H\%} = \left( \frac{C_0 - C_t}{C_0} \right) \times 100\%
\]

Where: 
- \(C_0\) is the initial dye concentration (ppm)
- \(C_t\) is the concentration of dye at time \(t\) (ppm)

**Result and discussion**

**Photocatalyst characterization**

The crystal structure and phase composition of the samples were characterized by XRD. As shown in Figure 2 (a), \(\text{g-C}_3\text{N}_4\) has two distinct diffraction peaks at 13.2ʰ and 27.3ʰ, which are corresponding to the (100) and (002) lattice planes (JCPDS 87-1526) [19]. The weak diffraction peak located at 13.2ʰ belongs to the in-plane repeat of tris-triazine and the stronger diffraction peak located at 27.3ʰ is attributed to the interlayer stacking of aromatic segments, respectively, indicating the fabricated \(\text{g-C}_3\text{N}_4\) has the characteristics of graphite [20]. The XRD patterns of 30-50% \(\text{g-C}_3\text{N}_4\)/HNT composites are similar to that of \(\text{g-C}_3\text{N}_4\), and the characteristic peaks of halloysite were observed at \(2\theta = 8.84ʰ, 22.96ʰ, 35.48ʰ\), which corresponded to the (001), (110), (122) [21]. The reduction in the intensity of the (100) peak in \(\text{g-C}_3\text{N}_4\) indicates the decreased planar size of the layer [22]. Consequently, 40% \(\text{g-C}_3\text{N}_4\)/HNT composite was used to evaluate the properties of the composite. The Fourier transformed infrared (FTIR) spectra (Figure 2 (b)) show that the peaks located at 1200-1700 cm\(^{-1}\) (C=N and C-N stretching vibration modes) [23]. The absorption bands at 3000-3500 cm\(^{-1}\) were assigned to the O-H of absorbed water and N-H of surface uncondensed amine groups. The peaks that appeared at 810 and 891 cm\(^{-1}\) could be attributed to the stretching vibration bands of the C-N to the characteristic breathing vibration of the triazine unit. This indicates that modification of \(\text{g-C}_3\text{N}_4\) by halloysite do not change the main feature of \(\text{g-C}_3\text{N}_4\).

The morphologies of halloysite support and 40% \(\text{g-C}_3\text{N}_4\)/HNT were observed by SEM and TEM images (shown in Figure 3). Figure 3 (a,b,e) show the pure HNT, it is clear that HNTs display a cylindrical-shaped tubular structure which aligned randomly, with the length of nanotubes are around 0.2-1.2 μm. It can be clearly observed that the surface of nanotubes is level and smooth. With 40% \(\text{g-C}_3\text{N}_4\)/HNT composite, the halloysite retained its nanotube morphology after the dispersal process while its outer surface became rough due to the deposition of \(\text{g-C}_3\text{N}_4\) as observed by SEM and TEM images (Figure 3 c,d,f).
Figure 3: SEM images of (a,b) HNT, (c,d) 40% g-C$_3$N$_4$/HNT composite. TEM images of (e) HNT and (f) 40% g-C$_3$N$_4$/HNT composite.

Figure 4: (a) N$_2$ adsorption-desorption isotherms at 77K and (b) the pore size distribution curves of halloysite, g-C$_3$N$_4$ and 40% g-C$_3$N$_4$/HNT composite.
Figure 4 displays the N$_2$ adsorption-desorption isotherms of the halloysite, g-C$_3$N$_4$ and 40% g-C$_3$N$_4$/HNT samples and the corresponding pore size distributions. As shown in Figure 4. (a), these three adsorption-desorption isotherms exhibit typical type IV profiles with distinct hysteresis loops of Type H4 according to the International Union of Pure and Applied Chemistry (IUPAC) classification, indicating mesoporous structures of these two photocatalysts. In addition, the pore size distributions of the halloysite, g-C$_3$N$_4$ and 40% g-C$_3$N$_4$/HNT samples display a wide range of pore diameter from 2-40 nm, suggesting the existence of mesopores. As shown in Table 1, the obtained BET specific surface area, average pore diameter, and pore volume of halloysite are 28.02 m$^2$.g$^{-1}$, 25 nm, and 0.14 cm$^3$.g$^{-1}$, which is higher than pure g-C$_3$N$_4$ (20.36 m$^2$.g$^{-1}$, 15 nm, 0.106 cm$^3$.g$^{-1}$), whereas those of 40% g-C$_3$N$_4$/HNT are 25.84 m$^2$.g$^{-1}$, 22 nm, and 0.17 cm$^3$.g$^{-1}$, respectively. It can be seen that the significant decrease in surface area and pore size of g-C$_3$N$_4$/HNT might be attributed to the filling of both micropores and mesopores of the halloysite by g-C$_3$N$_4$.

Figure 5: UV-vis absorption spectra (a) and Tauc plots of the UV-Vis spectra (B) of the as-prepared photocatalysts

In order to investigate the optical properties and band structure of as-prepared composite photocatalysts, the g-C$_3$N$_4$ and 30-50% g-C$_3$N$_4$/HNT were carried out by UV-vis diffuse reflectance spectra (DRS) in Figure 5. For the pure g-C$_3$N$_4$, a band edge is observed at 485 nm, which is consistent with previous reports [24]. Here, the estimated adsorption edge for 40% g-C$_3$N$_4$/HNT is 495 nm, which is significantly higher than those for 30% g-C$_3$N$_4$/HNT (492 nm) and 50% g-C$_3$N$_4$/HNT (489 nm).

The increased optical adsorption of g-C$_3$N$_4$/HNT should be attributed to the presence of halloysite nanotubes, which enhanced visible light adsorption ability, leading to the receiving of greater light irradiation in unit time. In addition, the band gap (E$_g$) of the as-prepared composite photocatalysts can be calculated from the following Kubelka-Munk equation:

\[
\alpha \nu = A(\nu - E_g)^{n/2}
\]

Where E$_g$ is the band-gap energy of the semiconductor, A is the adsorption constant, h is Planck’s constant, and \(\alpha\) and \(\nu\) represent the adsorption coefficient and the frequency, respectively, \(n=1\) for the direct transition. Therefore, the bandgap energies of the pure g-C$_3$N$_4$, 30-50% g-C$_3$N$_4$/HNT samples were obtained from a plot of \((\alpha \nu)^{1/2}\) versus \(\nu\) (Figure 5 (b)) as 2.63, 2.61, 2.60, 2.62 eV, respectively. The presence of HNT as a support, which contributed to the red-shift of the absorption onset, result in the narrow band gap of the g-C$_3$N$_4$/HNT composite.

https://doi.org/10.51316/jca.2021.064
Photoluminescence spectroscopy (PL) was implemented to investigate the carrier separation efficiency of photocatalytic composites. The higher intensity in the emission peak the more rapid recombination of the photoexcited electron-hole pairs [25]. As can be seen in Figure 6, the PL emission peaks at between 400 and 500 nm are observed in all the samples with the highest intensity observed in g-C$_3$N$_4$, followed by 30-50% g-C$_3$N$_4$/HNT, which is in good agreement with the analysis of UV-Vis DRS. The results indicate the enhanced separation rates of electron-hole pairs and the reduced charge transport distance in the composite.

**Photocatalytic activity test**

According to the previous study [26], halloysite can't be excited by visible light irradiation, but halloysite shows excellent adsorption ability with anion dyes. Because the inner surface of the halloysite tube is composed of Al-OH, which create electro-static attraction between O-H groups and SO$_3^-$ group of the Synozol red HF-6BN.

![Photoluminescence spectra of g-C$_3$N$_4$, and 30-50% g-C$_3$N$_4$/HNT photocatalysts](image)

Figure 7: Photodegradation of Synozol red HF-6BN under various reaction conditions of (a) mass contents of g-C$_3$N$_4$, (b) concentration H$_2$O$_2$, (c) photocatalytic dosages, (d) concentration of Synozol red HF-6BN

https://doi.org/10.51316/jca.2021.064
**Effect of g-C$_3$N$_4$ contents**

Figure 7 (a) illustrates the photodegradation rate of g-C$_3$N$_4$/HNT with different content of g-C$_3$N$_4$ via degrading Synozol red HF-6BN. From Figure 7 (a), the degradation of HF-6BN with various g-C$_3$N$_4$ content can be seen clearly that about 56% HF-6BN was degraded with g-C$_3$N$_4$ material after 30 mins under solar light irradiation, which might be due to the fast recombination of photogenerated electrons and holes and low surface area limiting the photocatalytic ability of the g-C$_3$N$_4$. In addition, the highest photocatalytic activity of 40% g-C$_3$N$_4$/HNT reached at 99% in 30 mins under solar light irradiation which is evidently higher than 30% g-C$_3$N$_4$/HNT (95%) and 50% g-C$_3$N$_4$/HNT (about 97%). These results are attributed to the excess mass of g-C$_3$N$_4$ agglomerates, preventing the formation of photogenerated electron-holes. Moreover, these indicating that the g-C$_3$N$_4$ compositied with HNT can actually enhance the visible light response ability and photocatalytic activity.

**Effect of H$_2$O$_2$ concentration**

The photocatalytic activity of the 40% g-C$_3$N$_4$/HNT catalyst was investigated during the photodegradation of Synozol red HF-6BN in the absence or presence of H$_2$O$_2$. As shown in Figure 7 (b), after 30 mins of irradiation with solar light, about 98% of HF-6BN was degraded in the presence of the 0.5 mL H$_2$O$_2$ and about 99% of HF-6BN was degraded by the presence of the 1 mL H$_2$O$_2$, while approximately 90% of HF-6BN was decomposed in the absence of H$_2$O$_2$. This result also implied that the assistance of H$_2$O$_2$ was needed for the degradation of HF-6BN over the g-C$_3$N$_4$/HNT.

**Effect of photocatalyst dosages**

The influence of the different dosages of 40% g-C$_3$N$_4$/HNT composite was also investigated under the same reaction conditions. Figure 7 (c) shows that the highest photocatalytic efficiency reached 99% after 30 mins corresponding to 100 mg of the catalyst. However, if the amount of catalyst continually increased, the interaction among the outer layers of the material reduced the photon formation of the inner layers, which led to a decrease in the number of e$^-$/h$^+$ pairs as well as the photocatalytic efficiency [27].

**Effect of Synozol red HF-6BN dye concentration**

The initial concentration of Synozol red HF-6BN was used to investigate photocatalytic activity of 40% g-C$_3$N$_4$/HNT as shown in Figure 7 (d). When the initial concentration of HF-6BN increased from 30 ppm to 70 ppm, the photocatalytic efficiency slightly decreased from 99% to 97%, implying that a high initial dye concentration could decrease the transmission opportunity and the part of the photon, thereby reducing the penetration rate of the solar light irradiation in the contaminant solution [28].

![Figure 8: Plot of (a) the pseudo-first order and (b) pseudo-second order kinetic model for the photodegradation Synozol red HF-6BN over 40% g-C$_3$N$_4$/HNT composite](https://doi.org/10.51316/jca.2021.064)
\[-\ln\left(\frac{C_t}{C_0}\right) = k_p t \quad (3) \text{ and } \frac{1}{C_t} - \frac{1}{C_0} = kt \quad (4)\]

Where $C_t$ and $C_0$ are the concentration at time $t$ and initial time, respectively, $k_p$ is the first-order reaction rate constant, $k$ is the pseudo-second-order reaction rate constant, and $t$ is the irradiation time. We observed in Figure 8 that the regression coefficient values for each concentration in the case of the pseudo-first-order kinetic model ($R^2 > 0.99$) was considerably higher than those of the pseudo-second-order kinetic model ($0.7 < R^2 < 0.86$).

The rate constant of the pseudo-first-order equation decreased from 0.2216 min\(^{-1}\) to 0.1143 min\(^{-1}\) when the initial concentration increased from 30 to 70 ppm. These results show that the photodegradation process was better represented by the pseudo-first-order model.

As discussed above, three main reasons for the increase in the photocatalytic efficiency of coupled g-\(\text{C}_3\text{N}_4\)/HNT composites are: (i) the absorption edges of g-\(\text{C}_3\text{N}_4\)/HNT composites shifts significantly to longer wavelengths compared with the pure g-\(\text{C}_3\text{N}_4\), which indicates the composites can be excited by more visible light photons; (ii) the enlarged BET surface of g-\(\text{C}_3\text{N}_4\)/HNT composites, the increased surface area offers more surface active sites for adsorption and photocatalytic reaction; (iii) The electrostatic interaction, the negatively charged halloysite can promote the immigration of electrons and holes, thus suppresses the charge recombination. The mechanism for the enhanced photocatalytic activity is illustrated in Figure 10. Considering the fact that halloysite is known as a very good electrical insulator, halloysite can't be excited and only g-\(\text{C}_3\text{N}_4\) can be activated, the electron-holes of g-\(\text{C}_3\text{N}_4\) have no opportunity to migrate to halloysite and still present on the g-\(\text{C}_3\text{N}_4\) surface. However, the excited electrons and holes of g-\(\text{C}_3\text{N}_4\) were driven to separate efficiently because the negatively charged halloysite surface restricted electrons transfer but favored holes migration. Thus, the charge recombination could be easily suppressed, leaving more charge carriers and enhancing the photocatalytic activity.
Conclusions

A novel g-C$_3$N$_4$/HNT composite was successfully synthesized via a calcination method. g-C$_3$N$_4$/HNT composites exhibited higher photocatalytic activity in the degradation of Synozol red HF-6BN. Specifically, the highest Synozol red HF-6BN degradation efficiency using 40% g-C$_3$N$_4$/HNT composite reached 99% after 30 mins under solar light irradiation. The significant enhancement in the photocatalytic performance of g-C$_3$N$_4$/HNT composites is ascribed not only to its adsorptive and enhanced absorptivity under visible light but also to the electrostatic interaction between g-C$_3$N$_4$ and negatively charged halloysite surface, this can promote the efficient migration of photogenerated electrons and holes of g-C$_3$N$_4$ and consequently improves the photocatalytic activity.
