**Keywords:**

**ABSTRACT**

The Mo-modified TiO$_2$ was synthesized via facile impregnation combined with pyrolysis of mixtures in several different initial mass ratios of precursors as $m_{Ti(OH)}:m_{(NH_4)MoO_2}e4H_2O$ equaling 5, 10 and 15 in 500 °C for an hour. The as-prepared samples, denoted as n-MT-500 within n for the initial mass ratio of precursors, were characterized by X-ray diffraction, scanning electron microscopy, ultraviolet-visible diffuse reflectance spectroscopy, Raman spectroscopy, as well as X-ray photoelectron spectroscopy, which all not only illustrate the presence of TiO$_2$ and MoO$_3$ components in the composites but also demonstrate the introduction of Mo hetero-atom into anatase lattice. All of the obtained samples performed higher photocatalytic activity under visible light than TiO$_2$ via the photodecomposition of RhB in aqueous solution, in which 10-MT-500 exhibits the highest degradation efficiency up to 87% after 5-hour illumination.

**Introduction**

Since the first time Fujishima and Honda published their work which inspired many scientists to conduct a variety of researches on the field of applying photo-catalytic activity of semiconductor for resolving global problems such as waste-water treatment, green energy generation, clean synthesis for chemical industry, etc., scientists still devote themselves to bring these methods from academic investigation to real application. Among oxide semiconductors, titanium dioxide, TiO$_2$, has attracted much attention of researchers in use as photo-catalyst due to its unique properties such as non-toxicity, low-cost, high photo and chemical stability and so on [1]. However, practical application of pure TiO$_2$ confronts a number of limitations with two main reasons. Firstly, the wide band gap of approximately 3.2 eV causes that TiO$_2$ is mainly activated under excitation of photons in UV region which only accounts for about 5% in the solar energy spectrum. In order to overcome this inherent objection, various efforts have been conducted to narrow band gap of TiO$_2$ via doping hetero-elements [2-4]. Secondly, the low photo-catalytic activity of TiO$_2$ could be attributed to the high-rated recombination of photo-induced charge carriers. For the purpose of surmounting this disadvantage, the strategy of coupling TiO$_2$ with other semiconductors, which own appropriate conduction band (CB) and valence band (VB) positions is a promising way to assist separation of photo-generated electron-hole pair then enhance the photo-reactivity of TiO$_2$ [5-8]. Among oxide semiconductors which are suitable for coupling with TiO$_2$, molybdenum trioxide, (MoO$_3$), as one of the most principal layered materials, is an ideal candidate due to its advantages such as high electron-stored ability [9], environmentally
friendly as well as relative narrow band gap of 2.85 eV [10] leading to absorption of onset-visible irradiation which is very beneficial for the photo-catalysis.

In this communication, we synthesized the composite of MoO\textsubscript{3}/TiO\textsubscript{2} with hierarchical electronic structure via the facile impregnation combined with calcination of precursors. Beside the forming of composites, the as-prepared samples were in a desire of Mo-doping into TiO\textsubscript{2} lattice, due to the smaller radius of Mo\textsuperscript{6+} compared to Ti\textsuperscript{4+}, leading to the reduction of the band gap.

**Experiments**

**Chemicals**
Ammonium molybdate tetrahydrate (NH\textsubscript{4})\textsubscript{6}Mo\textsubscript{7}O\textsubscript{24}.4H\textsubscript{2}O was purchased from China with purity of 99% and used directly without any further modification. Ilmenite ore, as the TiO\textsubscript{2} precursor was collected in Binh Dinh Province, Vietnam.

**Decomposition of Ilminite ore, Synthesis of TiO\textsubscript{2} and MoO\textsubscript{3}/TiO\textsubscript{2} composites**

The direct decomposition of Ilmenite ore collected in Binh Dinh, Vietnam, with chemical compositions presented in Table 1, was conducted via the procedure of Zenghe Li et al.[11] with some modifications. In a typical process, 50 g Ilmenite ore was added into concentrated solution of H\textsubscript{2}SO\textsubscript{4} in 500 ml three-necked flask then the mixture was stirred continuously in the range of 200 to 210 °C for an hour. The dark-purple obtained dispersion, as a solution of TiOSO\textsubscript{4}, was hydrolyzed and the collected precipitate, as Ti(OH)\textsubscript{4}, was used as Ti precursor for the next steps. The MoO\textsubscript{3}/TiO\textsubscript{2} composite was prepared via impregnation combined with pyrolysis in solid-state. In detail, the constant amount of ammonium heptamolybdate tetrahydrate was added into a 50 ml aqueous dispersion of Ti(OH)\textsubscript{4} within weight ratios of m\textsubscript{Ti(OH)\textsubscript{4}}/m\textsubscript{(NH\textsubscript{4})\textsubscript{6}Mo\textsubscript{7}O\textsubscript{24}.4H\textsubscript{2}O} equaling 5, 10 and 15. The obtained mixtures were stirred continuously at room temperature to evaporate solvent then treated the final solid in 500 °C for an hour. The as-prepared samples were denoted as nMT-500 in which n represents to the weight ratios of precursors. The pure TiO\textsubscript{2} was synthesized by the same procedure without Mo precursor and denoted as TiO\textsubscript{2}. For comparison, the collating sample of pure MoO\textsubscript{3} was synthesized by heating separately ammonium heptamolybdate tetrahydrate following the aforementioned process.

**Characterization**

Powder X-ray diffraction (XRD) patterns of samples were recorded by a D8 Advance X-ray diffractometer with Cu Kα radiation (λ = 1.540 Å) at 30 kV and 0.01 A. X-ray photoelectron spectroscopy (XPS) was obtained by ESCALab spectrometer (Thermo VG, U.K.). The SEM images of samples were recorded on Nova Nano SEM 450. UV-Vis diffuse reflectance spectroscopy (UV-Vis-DRS) was carried out on Cary 5000 (Varian, Australia). Raman spectra were recorded on T64000 Raman with a 633 nm laser as an excitation source.

**Photocatalytic Performance**

The photo-catalytic activity of all samples was investigated via the photo-degradation of RhB in aqueous solution under visible light irradiation. In a typical experiment, 0.1 g of nMT500 was added into 80 mL RhB solution with the initial concentration of 20 mg/L. The 220V-100W wolfram bulb with UV cutoff filter provided the source of visible light. Prior to irradiation, the suspension was continuously stirred in the dark for 1.5 hours to ensure the establishment of absorption – desorption equilibrium. At every irradiation time interval, about 10 mL of the suspension were taken up then centrifuged to remove the photocatalyst. The concentration change of RhB was measured at 553 nm wavelength on UV-Vis spectrophotometer (CECIL CE2011).

**Results and discussions**

**Characterization**

The XRD patterns of as-prepared samples were presented in Fig. 1. As shown in Fig. 1, the XRD pattern of TiO\textsubscript{2} includes peaks at 2θ = 25.35, 37.9, 48.09, 53.94, 55.06, 62.87, 69.0, 70.4 and 75.3° corresponding to the crystalline planes of (101), (004), (200), (105), (211), (204), (116), (220) and (215) which indicate the well-structured anatase phase of TiO\textsubscript{2} [2, 11-13]. The XRD pattern of collating sample MoO\textsubscript{3} shows peaks at 2θ = 23.4, 25.64, 27.3, 33.86, 39.03 and 49.33° which is consistent with crystalline planes (110), (040), (021), (111), (060) and (002) of orthorhombic MoO\textsubscript{3} (JCPDS Card no. 35-0609) [10], [14]. The nMT500 XRD patterns
also include mainly peak system of TiO$_2$ anatase phase while the characterizing signals of MoO$_3$ could be only seen at 23.4 and 27.3$\degree$, with weak intensity illustrating the low content of this component, which demonstrates that successful formation of MoO$_3$ insignificantly alters crystallite structure of TiO$_2$.

Figure 2: SEM images of TiO$_2$ (A) and 10MT500 (B)

The low content of MoO$_3$ in the composites, however, could be assigned to another role of incorporating into the TiO$_2$ lattice of Mo-element. According to Figure 1A, it is obvious to declare that most of the peaks characterizing for TiO$_2$ in composite XRD patterns become lower in intensity as well as broader compared to pure TiO$_2$. Actually, particle size of nMT500 (Table 1) calculated via Debeye–Scherrer equation is much smaller than that of bare component which could demonstrate that the introduction of Mo-constituent blocked the growth of TiO$_2$ particles [15–17].

This comment was also confirmed by SEM images in Fig 2. Accordingly, beside the existence of rod-like blocks which could be attributed to the layered MoO$_3$, SEM analysis of representative 10MT500 shows that, the surface of materials was surrounded by sphere-like particles of TiO$_2$ with much smaller size than pure TiO$_2$.

Furthermore, comparing to pure TiO$_2$, the highest intensity peak of (101) plane in nMT500 pattern shows a slight red shift to higher 2$\Theta$ illustrating the effect of inhibiting crystallite growth. Diminution of anatase crystallite quality could be attributed to the change of anatase lattice parameters. In detail, the lattice parameters as $a$ and $c$ of building unit of tetragonal anatase TiO$_2$ was estimated by Bragg’s law while the lattice distortion $\varepsilon$ of crystal was inferred via Williamson–Hall equation [18] $\varepsilon = \frac{\beta_{hkl}}{4\tan\theta_{hkl}}$ where $\beta_{hkl}$ is full peak width at half maximum of (hkl) plane at angle of $\theta_{hkl}$.

As shown in Table 1, despite the independence of lattice parameter $a$, the $c$ lattice constants as well as the interplanar spacing $d_{101}$ values are in direct proportion to the content of Mo-precursor, which could be ascribed to the incorporation of Mo atom into the anatase lattice. As the result of Mo$^{6+}$ radius (0.62 Å) [19] much smaller than Ti$^{4+}$ (0.68 Å) [16], Mo-atoms could occupy titanium position in crystallite units. In
addition, the increase of lattice distortion could be characterized for the introduction of Mo into TiO$_2$ lattice which could be confirmed in Table 1.

The further investigation on the structure of as-synthesized samples was conducted via Raman spectroscopy which is shown in Figure 3A. The spectra of 10MT500 show the highest peak of Eg signal located at Raman shift of 143.9 cm$^{-1}$ with a slight red shift compared to TiO$_2$. The other peaks at around 196, 393, 514 and 637 cm$^{-1}$ are corresponding to signals as E$_g$, B$_{1g}$, A$_{1g}$ and E$_g$ [20]. The absence of signals for Mo-O bonding combining the above XRD results could deduce the low content of MoO$_3$.

![Figure 3: Raman spectroscopy (A) and UV-Vis DRS (B) of TiO$_2$ and 10MT500](image)

The insertion of hetero-atom was in the desire of narrowing band gap of TiO$_2$. The reduction of band gap value could be estimated by UV-Vis DRS analysis. As shown in Fig. 3B, the absorbance of representative 10MT500 in visible light region is much higher than TiO$_2$ which is favorable for photocatalytic activity. Band gap values of samples were calculated by using Kubelka – Munk function [21] and shown in box of Fig. 3B. The pure TiO$_2$ exhibits a band gap of 3.12 eV which concurs with the value of previous reports [2-4], [22]. The modified TiO$_2$ as 10MT500 performs a clear red shift of band gap energy to around 2.89 eV which could be explained by the formation of charge transfer transition at bottom of conduction band of Mo atom [15-17].

In order to clarify the presence of Mo in as-prepared samples, the XPS analysis had been conducted and shown in Figure 4. Firstly, as shown in Fig. 4A, the Ti2p spectrum of TiO$_2$ include two peaks at a binding energy (BE) of 459.1 and 464.7 eV which are corresponding to the Ti$^{4+}$ of TiO$_2$ crystalline [16], [23]. In comparison to the TiO$_2$, two similar peaks in the Ti2p spectrum of representative 10MT500 located at 459.3 and 465.1 eV, which performs a slight shift to higher BE, indicates the substitution of Mo-atom into anatase lattice [16], [22] Secondly, in Fig. 4B, peaks at 232.4 and 235.6 eV are attributed to BE of Mo$^{6+}$ in which the difference between these peaks is 3.2 eV in agreement with previous reports [24], [25]. The other state of Mo$^{5+}$ could be confirmed by two peaks at 234.6 and 231.6 eV [12], [16]. In addition, the ratio of peak area between Mo$^{6+}$ and Mo$^{5+}$ (3.65) could estimate that the percentage of Mo$^{6+}$ and Mo$^{5+}$ are 78.5% and 21.5%, respectively. That means that most of Mo exists in samples is Mo$^{6+}$. The presence of Mo$^{5+}$ was an explanation for the aforementioned comment about the significant increase of lattice parameters a and c, in which most of the previous literatures recommend that due to larger radius of Mo$^{5+}$[22], [26]. Additionally, the formation of Mo$^{5+}$ could be clarified due to the state of oxygen insufficiency in anatase lattice [22].

![Figure 4: XPS analysis of TiO$_2$ and 10MT500](image)

The inadequacy of oxygen could be explained via the difference of O1s spectra between TiO$_2$ and 10MT500. The O1s core level spectroscopy, as shown in Fig. 4C, is the combination of a peak at 530.1 eV, ascribed to BE of anion O$^{2-}$ in TiO$_2$ lattice, and a slight shoulder at 531.7 eV, related to the form of absorbed oxygen. By contrast, the intensity increase of shoulder could be observed in the O1s spectrum of 10MT500. The increase of absorbed oxygen in modified sample could be clarified due to the deviation in oxygen coordination number of Ti$^{4+}$ and Mo$^{6+}$[16].

**Photo-catalytic activity**

Photo-degradation of RhB under illumination of the visible light source was presented in Fig 5. According to the results, all of the modified samples perform higher photodegradation efficiency of RhB than TiO$_2$ in
which 10MT500 exhibits the highest decomposition percentage up to 86.7% after 5-hour visible light irradiation. The enhanced photocatalytic activity of nMT500 compared to TiO$_2$ could be clarified by parallel effects. Firstly, the insertion of Mo-atom into TiO$_2$ lattice causes the forming more defects which act as trapping sites to decrease recombination of photogenerated charge carriers. This mechanism was discussed in another previous report of Osmín Avilés-García et al. [17]. Accordingly, after being excited to jump through band gap to the conduction band (CB), the photo-induced electron could be trapped by Mo$^{6+}$ to reduce it to Mo$^{5+}$ then extent lifetime of active species. In the next step, electrons could be donated to or trapped by absorbed oxygen or dye molecules to perform its reactivity. The content of Mo-precursors, however, reach an optimal ratio at 10MT500 then the photo-catalytic activity decrease with 15MT500 which could be explained by the fact that the over-increase of defects could lead to forming more recombination sites preventing the performance of active species [22], [27–28].

![Graph showing photo-degradation efficiency of all samples under 5-hour visible illumination](image)

Figure 5: Photo-degradation efficiency of all samples under 5-hour visible illumination

Secondly, the Mo-doping introduce an impurity level in the band gap which is close to the bottom of CB due to the similarity of orbital energy of Mo3d and Ti3d [29] leading to the narrowing its band gap as illustrating by aforementioned UV-Vis DRS analysis. Lastly, the formation of the second semiconductor of MoO$_3$ could construct a hierarchy energy band structure due to the appropriate CB and VB position of both components. Although pure TiO$_2$ only activated in the UV region due to its wide band gap [30], band gap between VB of TiO$_2$ and CB of MoO$_3$ estimated as 2.6 eV [31], [32] is confirmed that located in the visible region. Therefore, the photo-induced electron could be transferred directly from VB of TiO$_2$ to CB of MoO$_3$ though newly-formed Ti-O-Mo bonds [33]. In addition, the Mo-doped TiO$_2$ with narrower band gap could be activated by photons of onset visible light region to form photo-induced electrons and holes. Hence, the photo-induced electrons could transfer from CB of TiO$_2$ (-0.25 eV [34]) to more positive CB of MoO$_3$ (0.52 eV [35]) causing reduction of recombination of photo-induced charge carriers which is beneficial for photocatalysis.

**Conclusion**

In this work, we report the enhancement in photocatalytic activity of TiO$_2$ via modification by (NH$_4$)$_2$MoO$_4$ with facile impregnation synthesis combining heating treatment. All of the characteristic evidences illustrate the role of Mo as hetero-atom inserting in to anatase lattice in the main form of Mo$^{6+}$ beside the small amount of MoO$_3$ to create heterojunction structure. The results of photo-degradation testing with RhB of all samples demonstrate improvement in photocatalytic activity of modified samples in which the 10MT500 shows the highest efficiency. The mechanism of this enhancement within a few parallel effects had been discussed.
